ABSTRACT

All stars exhibit universal central behavior in terms of new homology variables (u, w) . In terms of these variables, we obtain simple analytic fits to numerical standard solar models for the core and radiative zones of the ZAMS and present Suns, with a few global parameters. With these analytic fits, different theoretical models of the solar core, neutrino fluxes, and helioseismic observations can be parametrized and compared.

Subject headings: Stars: interiors — Sun: interior — Sun: oscillations

To appear in **the Astrophysical Journal**: 10 November 1999

The complete static structure of a star of given composition profile involves two equations of mechanical equilibrium coupled to two equations of energy equilibrium. These must

¹ Based on a contribution to the Conference on Solar Neutrinos: News About SNUs, ITP/U. California at Santa Barbara, December 1997

be solved simultaneously to high precision, in order to predict neutrino fluxes and helioseismology. In this paper, we do not solve for a standard solar model (SSM) but instead fit a known standard solar model and helioseismic observations to analytical formulae, so as to understand simply the the energy- and neutrino-producing solar core.

We are helped by the fact that in cool, lower Main Sequence stars, temperature gradients are small. This practically decouples the centrally-concentrated inner core from the star’s extended radiative zone and convective envelope. Within the cores of such centrally-concentrated stars, the density and pressure profiles are, except for scale, determined by mass conservation and hydrostatic equilibrium. The other two equations, for energy production and transport, are essential in determining the thermal structure and the *normalization* of core mass and radius or, equivalently, of central density and pressure (ρ_c, P_c) .

We use homology invariants to isolate the dimensionless mechanical structure of any star whose barytropic structure $P(\rho)$ is known. We do *not* assume homology for the Sun or any part of it, but use the regular (E) solutions of the Lane-Emden equation only to illustrate our method.

Our fits do not describe the thermal structure or the whole Sun. Indeed, we must take the central density and pressure (ρ_c, P_c) from complete solar models or from helioseismic data. Because lower Main Sequence stars are nearly ideal gases, the ideal gas law $P/\rho = \Re T/\mu$ determines T/μ or the core’s thermal profile, once the composition profile is specified. Our best fits (Section 4) reproduce numerical SSMs to about a percent and can be used for the analysis of more-or-less model-independent helioseismic data. Indeed, helioseismology and the asteroseismology of Sun-like stars will ultimately *calibrate* solar models and may rule out severely non-standard SMs as a solution of the solar neutrino problem. The SM class homologous to the SSM is already ruled out because of its tight correlation between neutrino fluxes and central temperature, density, and nuclear cross sections (Bludman & Kennedy 1996, Hata & Langacker 1997).

1. Core Structure of Centrally-Concentrated Stars

1.1. Mechanical Structure Described by Homology Invariants

Homology-invariant variables were introduced by Chandrasekhar 1939 and Schwarzschild 1958 and are discussed, for example, by Cox & Giuli 1968 and Kippenhahn

& Weigert 1990. In place of the usual variables

$$u \equiv \frac{d \ln m}{d \ln r} \quad , \quad v \equiv -\frac{d \ln(P/\rho)}{d \ln r} \quad \text{or} \quad V \equiv -\frac{d \ln P}{d \ln r} = (n_e + 1)v \quad , \quad (1)$$

we choose

$$u \equiv \frac{d \ln m}{d \ln r} \quad , \quad w \equiv -\frac{d \ln \rho}{d \ln r} \equiv n_e v = \frac{V}{\Gamma} \quad , \quad (2)$$

in order to demonstrate universal density behavior (15) in the inner core. Here $\Gamma \equiv d \ln P / d \ln \rho \equiv 1 + 1/n_e$ defines the local polytropic index $n_e = d \ln \rho / d \ln(P/\rho)$, which is constant only for a polytrope. Although stellar structure is far from being self-homologous (polytropic), these homology-invariant variables have nevertheless historically proven to be useful.

Because the Sun is well-approximated by an ideal gas equation of state, $1 - \Gamma^{-1} \equiv 1/(n_e + 1) = d \ln(T/\mu)/d \ln P = \nabla - \nabla_\mu$, where $\nabla \equiv d \ln T / d \ln P$ and $\nabla_\mu \equiv d \ln \mu / d \ln P$ are the temperature and mean molecular weight logarithmic gradients. The barytrope $P(\rho)$ and n_e we are fitting both derive from the star's thermal structure and chemical composition. For cool stars like the Sun, n_e is not constant, but is large: the core is centrally concentrated and surrounded by extended radiative and convective zones. This fixes, to good approximation, the mechanical structure of the *inner core* of the Sun and other stars with extended envelopes.

The two mechanical equations

$$\frac{dm}{dr} = 4\pi r^2 \rho \quad , \quad -\frac{1}{\rho} \cdot \frac{dP}{dr} = g \equiv \frac{Gm(r)}{r^2} \quad , \quad (3)$$

for mass continuity and for pressure equilibrium, can be written respectively as

$$du/d \ln m = 3 - w - u \quad , \quad (4)$$

$$d \ln V / d \ln r = -1 + u + w/n_e \quad , \quad (5)$$

or

$$d \ln r = d \ln u / (3 - w - u) = d \ln V / [-1 + u + w/n_e] \quad . \quad (6)$$

The last equation (hydrostatic equilibrium) is a first-order equation for homology variables

$$\frac{d \ln(\Gamma w)}{d \ln u} = \frac{-1 + u + w(\Gamma - 1)}{3 - u - w} \quad , \quad (7)$$

provided Γ is a given function of u or w , determined by the prescribed thermal structure or barytrope $P = P(\rho)$. For continuously varying n_e or Γ , this is an extension of composite polytropes of different, constant $n_e = n$ (Chandrasekhar 1939).

In Section 4, we obtain u , w from the present and ZAMS standard solar models, including helium and metal diffusion, calculated by Bahcall, Pinsonneault and collaborators, and called the BP98 models. These are Bahcall, Basu, & Pinsonneault 1998 and Bahcall, Basu, Pinsonneault, & Christensen-Dalsgaard 1997 for the present Sun, and Pinsonneault 1998, for the ZAMS Sun. (See also Bahcall 1999.) We use the first (mass continuity) equation only to obtain the radial and mass distributions, $r(u)$, $m(u)$:

$$\frac{dm}{m} = u \cdot \frac{dr}{r} = \frac{dz}{w(z) - z} \quad , \quad (8)$$

where $z \equiv 3 - u = -d \ln \bar{\rho} / d \ln r$ and $\bar{\rho} \equiv m(r)/(4\pi r^3/3)$ is the average density interior to radius r . Since $d \ln g / d \ln r = u - 2 = 1 - z$, the gravitational acceleration $g \equiv Gm/r^2$ is a maximum at $u = 2$, and u , w have inflection points as functions of r , m . We define the *inner core* boundary as this radius: $u(\xi_{ic}) \equiv 2$ or $z(\xi_{ic}) \equiv 1$.

For regular solutions, $w \rightarrow 5z/3$ at $z = 0$. For solutions of *finite* radius, $w(z)$ diverges at the stellar surface

$$du/d \ln m \rightarrow -w \quad , \quad uV^{n_e} \rightarrow \text{constant} \quad , \quad z \rightarrow 3. \quad (9)$$

For solutions of *infinite* radius, w remains finite as $r \rightarrow \infty$. A centrally-concentrated core is insensitive to the stellar surface. In Section 3, we therefore neglect the outer boundary condition by letting w be finite at $z = 3$, so that the core radius recedes to infinity.

1.2. Polytropes as an Illustration

For comparison with analytic fits, we often study the polytropic case, $n_e = n = \text{constant}$, in which equation (7) reads

$$\frac{d \ln w}{d \ln u} = \frac{-1 + u + w/n}{3 - w - u} \quad \text{or} \quad \frac{d \ln w}{dz} = \frac{2 - z + w/n}{(3 - z)(w - z)} \quad . \quad (10)$$

Figure 1 shows the characteristic curves in the (u, w) plane for complete polytropes $P = K\rho^\Gamma$, in which $\Gamma \equiv 1 + 1/n$ is a constant fixed by the star's temperature gradient and $K = P_c/\rho_c^\Gamma$ is another constant determined by the star's total entropy or luminosity.

For polytropes, $w = n(-\xi\theta'_n/\theta_n)$, where $' = d/d\xi$, so that (3) give

$$\begin{aligned} (\xi^2\theta'_n)' + \xi^2\theta_n^n &= 0 \quad , \quad (11) \\ \theta &= (P/\rho)/(P/\rho)_c \quad , \quad \xi^2 \equiv r^2/\alpha^2 \quad , \quad \alpha^2 \equiv (n+1)R_0^2/6 \equiv (n+1)P_c/4\pi G\rho_c^2 \quad , \end{aligned}$$

the Lane-Emden equation of index n . We consider only the E-solutions, complete polytropes regular at the origin, for which $\theta_n = 1$, $\theta'_n = 0$ at $\xi = 0$.

In a polytrope, $\xi^2 \sim 5z/n \sim 3v$, so that $\xi_{ic}^2 \sim 5/n$. Therefore ξ_{ic}^2 is insensitive to n , for $3 < n < 5$. The stellar radius, however, diverges for $n = 5$. The constants of the Lane-Emden functions (Chandrasekhar 1939) imply $\xi_1 \simeq 3(n+1)/(5-n) \gg \xi_{ic}$, for $3 < n < 5$. Figure 1 shows that over this range in n , polytropes enjoy a common core structure and differ only by their more-or-less extended envelopes.

The two limiting cases of (10) are the polytropes $n = 0$ (incompressible matter) and $n = 5$ (the most centrally concentrated star of finite mass M). For incompressible matter, $m(r) = (4\pi/3)\rho r^3$, the exact solution is

$$\theta_0 = 1 - \xi^2/6 \quad , \quad P/P_c = \theta_0 \quad , \quad \rho/\rho_c = 1 \quad . \quad (12)$$

For the $n = 5$ polytrope,

$$\theta_5 = [1 + \xi^2/3]^{-1/2} \quad , \quad \rho/\rho_c = \theta_5^5 \quad , \quad P/P_c = \theta_5^6 \quad . \quad (13)$$

In the (u, w) plane, we have

$$u = \begin{cases} 3 \\ 3(1 - w/5) \end{cases} \quad , \quad z = \begin{cases} 0 & \text{for } n = 0 \\ 3w/5 & \text{for } n = 5 \end{cases} \quad . \quad (14)$$

These two limiting cases are the only ones for which u is linear in w . Examination of Figure 1 shows that all polytropes, and therefore all barytropes of finite mass, fall between these two limits.

The rest of this paper stresses the dominant role of mass continuity in the inner core of centrally-concentrated stars and uses equations (4–8) to extract the radial and mass profiles of the core from a realistic barytrope, which we take from the BP98 models or from helioseismic data. We solve only the first two (mechanical) equations of stellar core structure. The remaining two (thermal) equations of stellar structure, not considered here, determine the barytrope and luminosity and neutrino production.

1.3. Mass Continuity Determines Inner Core Structure

From mass continuity (8)

$$\bar{\rho}(r) = \rho_c^{2/5} \rho^{3/5}(r) \quad , \quad (15)$$

to first order in r^2 . For centrally-condensed stars ($n_e > 3$), this limiting behavior $w = (5/3)z$ remains a good approximation over the inner core $u > 2$, and leads to

$$u(m) \simeq 3 - (m/M_{ic})^{2/3} \quad , \quad m/M_{ic} \simeq (3 - u)^{3/2} \quad , \quad (16)$$

where M_{ic} is the inner core mass.

For the $n = 5$ polytrope, equation (16) holds exactly everywhere, the total mass M is finite and independent of the radius R , which is infinite. In this special case, the entire star is strictly homologous to the core. In centrally-concentrated non-polytropic stars, this remains approximately true: the dimensionless core profile is insensitive to the outer boundary condition, which only fixes the core scale.

Although not polytropic, all cool stars enjoy this common inner core profile: their low luminosity makes the temperature gradients small. Once (ρ_c, P_c) are specified, the core's structure is virtually determined by mass continuity and pressure equilibrium, rather than by their small energy generation and radiative transfer.

Defined this way, the inner core incorporates 97% (84%) of the ZAMS (present) Sun's luminosity production. We therefore fit over the *entire core* ($u > 1$, $z < 2$), constituting essentially all of the luminosity-producing region and about 65–70% of the Sun's mass. The parameters of the entire core are summarized in Table 2 and shown by vertical arrows in Figures 2–3. At the outer core radius, $w \sim 10/3$ for the present Sun and ~ 4 for the ZAMS Sun.

We use Schwarzschild dimensionless radius and mass defined in terms of the total stellar mass M and radius R (Schwarzschild 1958). When equation (8) is integrated,

$$m(z)/M = (z/3)^{3/2} \cdot \exp \left[\int_3^z dz \left\{ \frac{1}{w(z) - z} - \frac{3}{2z} \right\} \right] \equiv q(u) \quad , \quad (17a)$$

$$r(z)/R = (z/3)^{1/2} \cdot \exp \left[\int_3^z dz \left\{ \frac{1}{(3 - z)[w(z) - z]} - \frac{1}{2z} \right\} \right] \equiv x(u) \quad , \quad (17b)$$

after extracting the small- z behavior. The density is obtained by mass continuity (2) and (8):

$$\rho(z) = \rho_c \exp \left[- \int_0^z \frac{dz \, w(z)}{[w(z) - z](3 - z)} \right] \quad . \quad (18)$$

1.4. Central Density and Pressure Define Core Scale Factors

To first order in r^2 , hydrostatic equilibrium gives

$$P = P_c [1 - (r/R_0)^2] \quad , \quad (19)$$

where $R_0^2 \equiv 3P_c/2\pi G\rho_c^2$, a central radial scale R_0 determined by the central pressure and density and depending only implicitly on constitutive equations for equation

of state, opacity, and energy generation. We also define $M_0 \equiv (4\pi/3)R_0^3$, so that $(P/\rho)_c = GM_0/2R_0$, $P_c = (2\pi G/3)R_0^2\rho_c^2 = (3G/8\pi)(M_0^2/R_0^4)$. Table 1 summarizes the BP98 central values of P , ρ , and P/ρ for the ZAMS and present SSMs, and the central radial, mass and pressure scales derived therefrom.

Once ρ_c and outer boundary condition are given, P_c is determined. For given composition and constitutive relations, stellar structure then depends on only one parameter, the total mass M (Vogt-Russell Theorem), assuming no critical instabilities such as the Schönberg-Chandrasekhar limit (Kippenhahn and Weigert 1990). Integrating the equation of hydrostatic equilibrium,

$$P(u) = P_c - \int_0^u \frac{Gm}{4\pi r^4} dm = \frac{GM^2}{4\pi R^4} [\sigma_c - p(u)] \quad , \quad (20)$$

where $\sigma \equiv 4\pi R^4 P(u)/GM^2$ is the (Schwarzschild) dimensionless pressure defined by the total mass and radius,

$$\sigma_c \equiv 4\pi R^4 P_c / GM^2 \quad , \quad p(u) = \int_0^{3-u} \left[\frac{q(z)}{x(z)} \right]^2 \cdot \frac{dz}{[w(z) - z]} \quad . \quad (21)$$

Assuming a zero-pressure boundary:

$$\sigma_c = p(0) = \int_0^3 \left[\frac{q(z)}{x(z)} \right]^2 \cdot \frac{dz}{[w(z) - z]} = \frac{3}{2} \left(\frac{\rho_c}{\bar{\rho}} \cdot \frac{R_0}{R} \right)^2 \quad . \quad (22)$$

While $\rho_c/\bar{\rho}$ is a measure of *central* concentration relative to the *whole* star, $\sqrt{\sigma_c}$ is a better measure of *core* concentration. This is how, for a given barytrope, the inner and outer boundary conditions implicitly relate P_c to ρ_c or to (R, M) . The σ_c values for the BP98 ZAMS and present SSMs are displayed at the bottom of Table 1.

For polytropes, $\rho_c/\bar{\rho}$ and $\sigma_c \equiv 4\pi W_n \equiv 1/(n+1)[\theta'_n(\xi_1)]^2$ are tabulated (Chandrasekhar 1939). For $n = 0, 3, 4, 5$, $\rho_c/\bar{\rho}$ and $\sqrt{\sigma_c}$ equal 1, 54.2, 622., ∞ and $\sqrt{3/2}$, 11.8, 55.8, ∞ respectively. For the ZAMS (present) Sun, the values $\sigma_c = 88.7$ (260.) in Table 1, define equivalent values $W_n = 7.06$ (20.7) and polytropic indices $n = 2.796$ (3.256), indices for polytropes of the same core concentration σ_c . For polytropes, the integral theorem (22) reduces trivially to $1 = \theta_n^{n+1}(0) - \theta_n^{n+1}(\xi_1)$, or $\theta_n(\xi_1) = 0$, the implicit definition of the dimensionless polytropic radius ξ_1 .

2. The Standard Solar Cores

Standard solar models use the best opacities and heavy element diffusion to compute refined numerical results for solar neutrino fluxes and helioseismology over the whole

Sun. Figures 2(a,b), 3(a,b) respectively show the ρ and P/ρ profiles for the BP98 ZAMS and present standard solar models (Pinsonneault 1998), which include helium and metal diffusion, both normalized to central values. These figures also show our fits to the ZAMS (present) SSM cores derived from our hyperbolic approximation in Section 4 below. The central values of pressure, density and P/ρ for the ZAMS and present Suns are summarized in Table 1. The values at the core radius are summarized in Table 2.

In the homogeneous ZAMS Sun, $1 + n_e \equiv d \ln P / d \ln(P/\rho)$ is identical to $1 + N \equiv d \ln P / d \ln T \equiv 1/\nabla$ and varies from the almost adiabatic value 2.52 at $z = 0$ to a maximum value 5.21 at $z = 0.32$ ($r = 0.506$ of ZAMS solar radius). Where the radiative zone meets the convective core, $1 + n_e$ shows a discontinuity in slope. The pressure-averaged value over the whole ZAMS Sun is $n_e \approx 3$.

In the course of stellar evolution, the molecular weight gradient ∇_μ has increased from the original value $\nabla_\mu = 0$ to the present value at the center, $\nabla_\mu = 0.41$. Meanwhile, the thermal gradient ∇ has decreased, so that, at present, $\Gamma \sim 1$ (Bludman & Kennedy 1996). In the present inner core, P/ρ has a maximum ($v = 0$ or $\Gamma = 1$) at $z_{\text{peak}} = 0.36$, $m/M_\odot = 0.034$, $r/R_\odot = 0.073$. Inside this zone, $\nabla_\mu > \nabla$ ($\Gamma < 1$), and $w(u)$ has a slight negative curvature, seen in Figure 5(c). ∇_μ decreases radially from 0.41 at $z = 0$ to zero at the edge of the core. Γ increases from $\Gamma_c = 0.86$ to 1.31, then slowly declines through most of the outer radiative zone.

For the *whole* ZAMS (present) Sun, the central concentration $\rho_c/\bar{\rho} = 35.3$ (108) would imply *global* effective polytropic indices $n \simeq 2.76$ (3.35). But the Eddington $n = 3$ Standard Model is a only crude approximation to the whole present Sun. The off-center P/ρ peak shows that any polytropic approximation must fail badly in the present inner core, which shows *more* central concentration than does the whole Sun. This inner core determines neutrino production and g -wave helioseismology.

3. Analytic Approximations for Centrally-Concentrated Stellar Cores

We now parametrize the BP98 SSMs by analytic formulas that incorporate the central boundary condition. Because they neglect the outer boundary condition (9), these approximations are applicable only inside the core. The mechanical structure of any star is represented by a (u, w) curve asymptotic to $w = (5/3)(3 - u) = 5z/3$ near the center $u = 3$, $w = 0$ and curving upwards for $u \rightarrow 0$. The straight-line behavior is a good approximation only in the inner core ($u \gtrsim 2$) of centrally-concentrated cores, and needs to be corrected in the outer core.

3.1. Hyperbolic Approximation

Some of the upward curvature of $w(z)$ is captured by a simple “hyperbolic” approximation to the core of an extended polytrope

$$w(u) = (5/J)[1 - (u/3)^J] \quad , \quad w(z) = (5/J)[1 - (1 - z/3)^J] \quad , \quad (23)$$

where $J = (9n - 10)/7n$. At $u = 0$, $w = 5/J$ is finite for any $J > 0$, making the radius infinite.

Within the core, this one-parameter hyperbolic form is a closed approximation to a polytrope. The form (23) is a Picard iterate (Boyce & DiPrima 1992) of equation (7). Integrating $w/n = -\xi\theta'_n/\theta_n$, equation (23) gives

$$w(\xi) \approx (n\xi^2/3)/(1 - \xi^2/6N) \quad , \quad \theta_n(\xi) \approx [1 - \xi^2/6N]^N \quad , \quad (24)$$

where $N \equiv 5/(5 - 3n)$. This elementary representation of Lane-Emden functions is exact for $n = 0$ ($N = 1, J = -\infty$) and for $n = 5$ ($N = -1/2, J = 1$). For intermediate n , the expansion of our approximation (24) gives

$$\theta_n(\xi) \approx 1 - \xi^2/6 + n\xi^4/120 - n(6n - 5)\xi^6/10800 + \cdots \quad , \quad (25)$$

which agrees with the exact Lane-Emden function (Cox & Giuli 1968)

$$\theta_n(\xi) = 1 - \xi^2/6 + n\xi^4/120 - n(8n - 5)\xi^6/15120 + \cdots \quad , \quad (26)$$

through fourth order in ξ . The ξ^6 coefficient in the hyperbolic approximation is $7(6n - 5)/5(8n - 5)$ times that in the exact Lane-Emden function, or 0.985 for $n = 4$. At least for polytropes with $3 < n < 5$, the inner core ($z \leq 1$) is well-approximated by the hyperbolic approximation (23). The corresponding Taylor series

$$w(z) = (5z/3)[1 + (5 - n)z/21n + \cdots] \quad (27)$$

converges only for small z . The hyperbolic form is not intended to apply outside the core in any case.

3.2. Generalized Parametric Forms for Improved Pressure Structure

If n_e were constant, repeated Picard iteration of (7) would improve the hyperbolic approximation (23), with better convergence for larger z and better approximation to $\theta_n(\xi)$. However, this refinement diverts us from considering a real star, where n_e is not constant.

This departure from homology is especially important for describing helioseismology and neutrino production in the present solar core.

In the non-polytropic case, equation (7) becomes

$$\frac{d \ln(\Gamma w)}{dz} = \frac{2 - z + w(\Gamma - 1)}{(3 - z)(w - z)} . \quad (28)$$

The power of homology variables becomes evident when we construct non-polytropic approximations to $w(z)$. The most straightforward approach is to substitute an ansatz for $\Gamma(z)$, integrate (28) to obtain $w(z)$, and then deduce the desired structural profiles. The simplest non-trivial ansatz, a piecewise linear function for $\Gamma(z)$, suffices for the present Sun:

$$\Gamma(z) = \begin{cases} \Gamma_c + (z/z_{\text{peak}})(1 - \Gamma_c) & , \quad z < a \\ \Gamma_c + (a/z_{\text{peak}})(1 - \Gamma_c) + b(z - a) & , \quad z > a \end{cases} , \quad (29)$$

where the parameters Γ_c , z_{peak} , a , and b obtained from BP98 are given in Table 3.

Once equation (28) is solved for $w(z)$, from equation (17b) and the definition of Γ ,

$$\begin{aligned} r(z) &= R_0 \cdot [(5\Gamma_c/2)(z/3)]^{1/2} \cdot \exp \left[\int_0^z dz \left\{ \frac{1}{(3 - z)[w(z) - z]} - \frac{1}{2z} \right\} \right] , \\ P(z) &= P_c \cdot \exp \left[- \int_0^z \frac{dz \, w(z) \, \Gamma(z)}{[w(z) - z](3 - z)} \right] . \end{aligned} \quad (30)$$

All the non-trivial information and sensitivity of boundary conditions is now contained in this pressure integral.

4. Analytic Fits to the SSM Cores

We now fit the preceding hyperbolic and parametric forms to the entire core of BP98, which includes all of the energy and neutrino producing parts of the Sun. The BP98 models have finer zoning near the center of the star, where, as we have shown, the mechanical structure is universally governed by mass continuity. To correct for this over-representation of the central region and to make our fits sensitive to the non-trivial outer core structure, we weight the BP98 data points inversely by their density in the (u, w) plane. The local density is the number of model points per arc length of (u, w) curve.

Table 3 summarizes our best fits (23,29) to the ZAMS and present Suns and their root mean variances (r.m.v.'s), the root of the sum of squared deviations of fit and SSM model points, normalized by the degrees of freedom in the fit. Each hyperbolic fit can

each be interpreted in terms of an equivalent stiffness $\langle \Gamma \rangle$ or polytropic index $\langle n \rangle$ averaged over the core. Figures 4, 5 show the BP98 data points and our hyperbolic (hyperbolic and parametric) fits in the ZAMS (present) Sun.

For the BP98 ZAMS SSM, Figures 4(a,b,c) show $u(m)$, $w(m)$, $u(w)$ together with our hyperbolic fit (dashed curve in Figure 4c) to the 94 data points in the radiative zone $u > 1$. Because the innermost core of the ZAMS Sun has still not evolved far from its convective beginning $\Gamma \approx \Gamma_{\text{ad}} = 5/3$, the ZAMS core is approximated by a rather stiff $\langle n \rangle = 1.8$ polytrope. Figure 4(d) shows the variation of $\Gamma(z)$ over the ZAMS core. Our hyperbolic approximation is sufficiently accurate: using a general parametric form would lead to no improvement in the fit.

Figures 5(a,b,c) show the BP98 SSM present solar core, together with our hyperbolic fit (dashed curve in Figure 5(c) to their 95 data points in the radiative zone $u > 1$. Within its large uncertainty in $\langle n \rangle$, the hyperbolic fit (Table 3) is consistent with the Eddington $n = 3$ Standard Model. This *global* agreement with the Eddington model, however, misses the crucial *local* feature of the present solar core. As seen in Figure 3b, the present Sun has evolved a broad off-center maximum in P/ρ at $r/R_{\odot} = 0.073$, $m/M_{\odot} = 0.034$, which cannot be described by any polytrope or other one-parameter function. Indeed, n_e is infinite at this maximum in P/ρ and negative (positive) inside (outside) this zone, explaining the large uncertainty in $\langle n \rangle$ obtained by the simple hyperbolic fit. Although n_e is singular, Γ varies smoothly through unity at the peak in P/ρ at $z_{\text{peak}} = 0.36$, as shown in Figure 5(d).

The parametric best fit in Table 3 is six times better than the hyperbolic best fit. The resulting improved profiles of w , ρ , and P are shown by the solid curves of Figures 3 and 5. The improvement in the double logarithmic derivative $w(u)$, although it appears small to the eye, is important: with it, we get an excellent fit to P/ρ in the present solar core.

5. Analytic Fit to Helioseismological Observations

We now fit to helioseismic data from the present Sun and the inferred adiabatic squared sound speed $c_{\text{ad}}^2 = \Gamma_{\text{ad}} \cdot (P/\rho)$, where $\Gamma_{\text{ad}} \equiv (\partial \ln P / \partial \ln \rho)_{\text{ad}}$. Hydrostatic equilibrium (3) gives the the slope of the sound speed:

$$\frac{dc_{\text{ad}}^2}{dr} = -g\Gamma_{\text{ad}}(1 - \Gamma^{-1}) + \frac{P}{\rho} \cdot \frac{d\Gamma_{\text{ad}}}{dr} \quad . \quad (31)$$

In the inner core of the present Sun, the local g is well-determined by mass continuity, but $(1 - \Gamma^{-1}) = 1/(1 + n_e)$ varies greatly, because of the evolved molecular weight gradient ∇_{μ} .

The p -mode sound speed (Figure 6, Basu et al. 1997, and Christensen-Dalsgaard 1997)

has been inferred from comparison of solar models (Christensen-Dalsgaard et al. 1985) and helioseismic observations now reaching virtually to the solar center (Christensen-Dalsgaard et al. 1996; Gough et al. 1996; Kosovichev et al. 1997; Basu et al. 1997; GONG Collaboration 1999; SOI Collaboration 1999). Assuming only spherical symmetry, mass continuity, pressure equilibrium and full ionization in the core ($\Gamma_{\text{ad}} = 5/3$), $dc_{\text{ad}}^2(0)/dr$ must vanish, and we fit the 22 points $r < (0.32)R_{\odot}$ in Figure 6 to a polynomial in r^2 to obtain the central sound speed. Our best fit is ninth order in r^2 and gives

$$c_{\text{ad}}(0) = (5.07 \pm 0.09) \times 10^7 \text{ cm sec}^{-1}, \quad (32)$$

in excellent agreement with the BP98 present Sun SSM value of $5.053 \times 10^7 \text{ cm sec}^{-1}$ (negligible error). $c_{\text{ad}}^2(0)$ fixes $\sigma_c(\bar{\rho}/\rho_c) = R_{\odot}c_{\text{ad}}^2(0)/GM_{\odot}\Gamma_{\text{ad}} = 0.81 \pm 0.03$.

6. Conclusions

The BP98 ZAMS and present SSMs are well described by the analytic and semi-analytic formulas (23,24,28–30,18). Because it is still partly convective, the core of the ZAMS Sun (Figures 2, 4) is globally approximated, with root mean variance 0.1, by a stiff polytrope of $\langle\Gamma\rangle = 1.6 \pm 0.1$, $\langle n\rangle = 1.8 \pm 0.2$.

The core of the present Sun (Figures 3, 5) is only crudely polytropic with index $\langle n\rangle = 3.4 \pm 1.0$ and root mean variance 0.1 (Figure 5). The inhomogeneous inner core requires a variable $1 - \Gamma^{-1} = \nabla - \nabla_{\mu}$. A parametric form that generalizes the polytrope to a linearly varying Γ accurately fits the present solar core.

Helioseismological data can be analyzed in the same phenomenological approach, ultimately extensible to a fully model-independent framework. Present data do not allow an *independent* reconstruction of inner core structure, but future measurements of g modes and refinement of p -mode data should allow further iteration of full numerical models or refinement of our parametric approach (28–31) with varying Γ . Asteroseismology can be similarly analyzed.

We thank Marc Pinsonneault of Ohio State University for the BP98 SSM tables, and John Bahcall of the Institute for Advanced Study, Princeton, and Jørgen Christensen-Dalsgaard of the Institute of Physics and Astronomy, Aarhus University, Denmark, for helioseismology data. This work was supported by the U.S. National Science Foundation under grant PHY89-04035 (U. California, Santa Barbara), the U.S. Department of Energy under contracts DE-FG05-86-ER40272 (Florida) and DE-AC02-76-ERO-3071 (Penn), and by the Institute for Fundamental Theory (U. Florida).

FIGURES

Fig. 1.— The characteristic $w(u)$ curves of the mass and density logarithmic derivatives, for complete polytropes $n = 0, 1, 2, 3, 4, 5, \infty$. All stars satisfy the central boundary condition $w \rightarrow (5/3)(3 - u)$. Centrally-concentrated stars ($n > 3$) show this common structure inside an inner core defined by $2 \leq u \leq 3$ (up to maximum gravitational acceleration). The total mass and radius are finite for each polytrope $n < 5$. The $n = 5$ polytrope has infinite radius for every finite mass.

Fig. 2.— The mechanical structure of the BP98 ZAMS Sun: (a) density with central value $\rho_c = 74.7 \text{ g cm}^{-3}$ and (b) pressure-density ratio with central value $(P/\rho)_c = 1.83 \times 10^{15} \text{ cm}^2 \text{ sec}^{-2}$. Dashed curves: same properties for our hyperbolic best fit. Vertical arrows: outer core radius defined by $u = 1$.

Fig. 3.— The mechanical structure of the BP98 present Sun: (a) density with central value $\rho_c = 152. \text{ g cm}^{-3}$ and (b) pressure-density ratio with central value $(P/\rho)_c = 1.53 \times 10^{15} \text{ cm}^2 \text{ sec}^{-2}$. Dashed curves: same properties for our hyperbolic best fit. Solid curves: same properties for our parametric best fit. Vertical arrows: outer core radius.

Fig. 4.— The BP98 ZAMS Sun in terms of homologous variables (u, w) : (a) u as function of mass fraction $m/M_\odot$; (b) w as function of mass fraction $m/M_\odot$; (c) parametric plot of $w(u)$; (d) variable $\Gamma(z)$. Our hyperbolic best fit (dashed curves) is an adequate fit to the ZAMS core.

Fig. 5.— The BP98 present Sun in terms of homologous variables (u, w) : (a) u as function of mass fraction $m/M_\odot$; (b) w as function of mass fraction $m/M_\odot$; (c) parametric plot of $w(u)$; (d) variable $\Gamma(z)$. Our hyperbolic best fit (dashed curves) is unacceptable. Our parametric best fit (solid curves) is much better than the hyperbolic fit to the present solar core.

Fig. 6.— The p -mode adiabatic sound speed in core of Sun inferred by linearized perturbative inversion from helioseismic observations and a reference SSM. Uncertainties too small to show. Solid curve: our parametric best fit. (Data courtesy of J. Christensen-Dalsgaard.)

	<i>ZAMS Sun</i>	<i>Present Sun</i>
P_c (10^{17} dyn cm $^{-2}$)	1.37	2.33
ρ_c (gm cm $^{-3}$)	74.7	152.
P_c/ρ_c (10^{15} cm 2 sec $^{-2}$)	1.83	1.53
R_0/R	0.218	0.122
M_0/M	0.366	0.196
$GM^2/4\pi R^4$ (10^{15} dyn cm $^{-2}$)	1.54	0.895
σ_c	88.7	260.
$\rho_c/\bar{\rho}$	35.3	108.
n	2.796	3.256

Table 1: Central pressure, density, pressure scale height, and other features of the BP98 ZAMS and present SSMs. The global quantities below the horizontal line describe ZAMS and present Suns of total mass $M = M_\odot = 1.989 \times 10^{33}$ gm and radii $R = (0.873)R_\odot$, $R_\odot = 6.96 \times 10^{10}$ cm respectively. $\rho_c/\bar{\rho}$ and σ_c are measures of central and core concentration for the entire Suns. n is the polytropic index of a complete polytrope showing same value of σ_c .

	<i>ZAMS Sun</i>	<i>Present Sun</i>
R_0/R	0.218	0.122
r_g/R_0	1.86	2.67
r_g/R	0.404	0.326
m_g/M	0.711	0.666
L_g/L	1.00	1.00
w_g	4.05	3.67

Table 2: Entire core mass m_g , radius r_g , luminosity L_g and homology invariant w_g of BP98 ZAMS and present SSMs. Total mass, radii, and luminosities of the ZAMS and present Suns are $M = M_\odot = 1.989 \times 10^{33}$ gm; $R = (0.873)R_\odot$, $R_\odot = 6.96 \times 10^{10}$ cm; and $L = (0.679)L_\odot$, $L_\odot = 3.84 \times 10^{33}$ erg sec $^{-1}$ respectively. Entire core is defined by $u_g = 1$.

<i>Type of Fit</i>		<i>ZAMS Sun</i>	<i>Present Sun</i>
Hyperbolic	J	0.5 ± 0.1	0.9 ± 0.1
	$\langle n \rangle$	1.8 ± 0.2	3.4 ± 1.0
	$\langle \Gamma \rangle$	1.6 ± 0.1	1.3 ± 0.1
	r.m.v.	0.097	0.10
Improved General Para- metric	Γ_c	1.66	0.86
	z_{peak}	—	0.33
	a	—	1.09 ± 0.01
	b	—	-0.07 ± 0.02
	r.m.v.	—	0.016

Table 3: One-parameter hyperbolic and four-parameter generalized parametric fits to BP98 ZAMS and present SSMs. $\langle n \rangle$ and $\langle \Gamma \rangle = 1 + 1/\langle n \rangle$ are index and stiffness of polytropes having the same *average* core properties. Below the line, the four parameters describing variation of $\Gamma(z)$ give a much improved fit for present solar core.

Homology Invariants for Polytropes n
